DATED 6 APRIL 1981..

S

The undersigned certify that they have read, and recommend to the Faculty of Graduate Studies and Research, for acceptance, a thesis entitled Stability Analysis in Underground Hydraulic Mining submitted by H.J.Lutley in partial fulfilment of the requirements for the degree of Master of Science.

Date... Apr. 6, 1981.....

Abstract

The current rapid expansion of the Western Canadian coal mining industry will include the extraction of steeply dipping seams in the foothills and mountain region.

A computer model has been developed to investigate induced stresses in various sub-level mining configurations. It utilizes a linear elastic finite element analysis and provides graphical output to identify stress concentrations and possible areas of instability. The results from the numerical analysis were compared with a physical model analysis and observations in operating mines, and were found to be compatible. Zones of high stress concentration and areas suitable for future development were located.

ACKNOWLEDGEMENTS

I wish to thank my family and friends, and staff and colleagues at the University of Alberta for their support and encouragement during the completion of this project. Particular thanks are due to Dr.M.Jeremic who supervised my studies.

I would also like to acknowledge the financial support provided by Gulf Canada Resources Inc. and the permission granted by them, and Denison Mines Ltd., to use property data gathered on one of their mining leases.

1. Introduction

1.1 Coal Reserves

Western Canada produces approximately ninety percent of total Canadian coal output but of this less than ten percent is by underground methods.¹ Table 1 indicates the present estimated reserves and Figure 1 shows their distribution.² Approximately eighty-five percent of the high grade, low sulphur coking reserves of the mountain region of Alberta are mineable by underground methods and the remainder by open-pit. Since reserves in the mountain region accessible by surface methods are rapidly being depleted, underground reserves and consequently underground methods will become more important. Up to seventy percent of the valuable coking coal reserves of western Alberta and northeastern British Columbia are contained in the steeply dipping seams of the foothills and mountain region. This region is characterized by a high degree of tectonic disturbance leading to shear zones in the coal, slickensided surfaces in the adjacent strata and thrust faults at low angles to bedding throughout the coal series. The seams tend to be unstable and consist of bands of hard and soft coal; this banding is due in part to the petrographic composition and also to the tectonic history of the seam.

1.2 Available Technology for Extraction from Tectonically Disturbed Seams

Current production by the underground mining of tectonically disturbed seams in western Canada is limited because until recently the relatively easy access to supplies of high quality coking coals in other countries restricted the development of the mountain region. However with depletion of other reserves the western Canadian seams become economically more favourable. The room and pillar mining method is the most common and is practiced at the McIntyre Mines Ltd. Grande Cache operation and was practiced at Coleman Collieries operations in southern Alberta until their recent closure. Continuous miners are used for development and production³ and belt conveyors for underground transportation of the coal. The room and pillar technique is suited only to gently dipping seams and if there is considerable tectonic disturbance in the coal and adjacent strata, large pillars and a thick coal floor have to be left which decrease overall recovery rates.

Mechanised longwall mining has not been operated in western Canada although McIntyre Mines experimented with this technique. Longwall mining in inclined thick seams is practiced successfully in the Blanzky coalfield in France.⁴ Combinations of shield supports, artificial roofs and coal caving are utilised. Longwall methods are used in the United States and have been investigated for application to thick seams.⁵

The third technique currently used underground is sub-level caving. This is practiced in the Loire and Auvergues coal fields in France and at the Michel colliery in the Crow's Nest Basin in southeastern British Columbia.⁶ The French practice a horizontal slicing method with sub-level caving of an intermediate slice of coal. This method allows the mining of very irregular steep seams with good results and proceeds down dip with caving occurring above the worked slice. Other techniques working up dip include hydraulic stowing of the mined out area to improve stability and reduce the risk of spontaneous combustion.. At the Michel colliery operated by Kaiser Resources Ltd. sub-level hydraulic mining is used. This replaced a more conventional drilling and blasting sub-level mining technique. Sub-level blocks or panels are developed with continuous miners and these are subsequently extracted by hydraulic monitors. Coal transportation is also by water through pipes and flumes on the roadway floors. This method has proved to be safe and productive increasing the overall recovery rate from fifteen to fifty-five percent. Because of the success of this technique in western Canadian conditions, and the growing interest in sub level hydraulic mining, it was decided to concentrate the research on this mining method.

1.3 Research Methods

The design concepts used in this research project utilise accepted mine analysis and planning techniques. Because of the temporary nature of many mine excavations (e.g. production sub-levels) design and planning is aimed to obtain the most cost effective solution for the excavation's projected life. Thus an excavation's cost will not only include the ground breakage and support costs but also maintenance to keep it in such a condition that operations can continue. This requires an optimisation of initial support costs against maintenance costs and often leads to a minimum of support and an allowance for maintenance during the life of the excavation. In contrast Civil Engineering structures, for example, which are normally of a more permanent nature, (e.g. road tunnels) are designed with long term stability as an objective, and as a result may require greater detail in design and analysis. This level of detail is rarely required in mine design because of the flexibility in choice of geometry and the possibility of solving local instability problems by additional support which maybe of a temporary nature. In consequence the research and design techniques utilised in mining and civil engineering are often similar (e.g. mathematical modelling) but the depth and detail of a pre-mining engineering study may be of a lesser degree.

A further problem encountered in deep, underground mining is the variation in rock properties with depth and

from to place to place. Exploration drilling cannot provide enough detail to define all geological structures underground. Also sampling and physical property testing procedures cannot completely define the behaviour of the rock materials. Therefore any research must recognize and work within the limits of the data. In the research program, which is the subject of this thesis, little initial data was available, so the analytical techniques utilise simplifying assumptions which will be described as they are encountered.

2. Factors Influencing Mine Model Design

2.1 Geological

The main geological factors influencing mineability and choice of mining method are related to the geometry of the deposit, the nature of the surrounding strata and the petrographic composition of the coal. For this study which is concerned with steeply dipping seams it has been assumed that seam inclination is greater than 25° and that therefore conventional room and pillar or longwall mining is not possible. Also it can be assumed that seam thickness is sufficient to permit economic extraction by sub-level hydraulic mining.

The lithology of the mountain formations is generally comprised of thin- to thick-bedded sandstones, siltstones, mudstones and shales with interbedded coal seams.⁷ The fine to coarse grained clastics vary in colour from light grey to black. The coal seams of the Kootenay Formation of southern B.C. are remarkable for their thickness and continuity. Thicknesses vary up to fifty feet of coal and more than thirteen seams greater than four feet in thickness have been identified. In other formations in the foothills region (Luscar, Commotion, Gething) seams tend to be less continuous due to the lensing nature of the coal bearing beds, and because of the complexly folded and faulted structure of the foothills strata. As is to be expected in an area of such structural disturbance the seams are

normally steeply inclined and in some instances severely contorted, thickened or thinned, cut off by faults, and the coal so severely crushed as to make it extremely friable. In other instances, however, these structures have so oriented the seam with respect to the surface, or so thickened the seam that excellent recovery can be made by strip mining.⁸

At the Michel colliery, Sparwood, a fifty foot thick seam known locally as the Balmer seam is currently being extracted by sub-level methods. Its average dip is 35° and the adjacent strata consists of shales and sandstones which provide a competent roof. Since mining has proved feasible under these conditions the choice of mining configurations for the theoretical modelling of this thesis was influenced by the geological structures observed in this mine which have been described in the literature.¹⁰

The strength and deformational behaviour of coal is briefly described in section 2.3 but since it is related to the petrography of the seam a short description is included here. Using the Stopes-Heerlen classification a particular coal can be described on a macroscopic level in terms of the lithotypes vitrain, clarain, durain and fusain. These macroscopic forms correspond to the bright, dull, hard and soft bands seen in a seam section. Structurally fusain is the softest coal type, vitrain is stronger but brittle, clarain is mechanically strong and durain is the strongest. Table 2 shows the petrography of a western Canadian seam in the Kootenay Formation.⁹ The predominant lithotype of this

section is clarain with vitrain and durain present as interbands. Apart from the roof and floor coal, the seam, if undisturbed, would appear to be structurally strong because of the presence of firm clarain and durainous clarain bands. This type of information may be relevant to mine design when considering strength of coal pillars and their modes of failure provided that the seam has not been severely disturbed by tectonic action. The investigation into strength and deformational properties of coal and other strata and the values used for modelling is described in section 2.3.

2.2 Mining

Within a particular method chosen for extraction of a coal deposit modifications can be made to increase recovery, mineability and stability. Four different configurations were analysed using the mathematical model but the overall layout, dimensions and depth were similar for each of these sub-level caving methods.

The sub-level hydraulic mining method used at the Michel colliery is outlined here because the basic layout of this mine would be similar to other sub-level coal operations. Development is by continuous miners feeding directly into a flume line with the coal being washed down by water chute. Two main entries are driven to the rise at 7' at an acute angle to strike.¹⁰ Crosscuts at 800 foot intervals connect the main entries to establish a

ventilation circuit and simplify access. Sub-levels inclined at about 9° are turned off the main entries at an angle of approximately 155°. These sub-levels are on 80 foot centres and are kept as close to parallel as conditions will allow, (Fig.2). Support is by 16 x 10 foot timber lagged steel arches at five foot intervals. The three sub-levels furthest in-by are equipped with a feeder-breaker and monitor and the necessary pipes and flumes. Since belt-conveyors are not used in the mine straight line drivages are not essential but careful control of gradient is necessary.

Bulk production is achieved using high pressure water fed through the monitor which is mounted on the feeder-breaker. The monitor is remotely controlled by the operator from a small cabin which is at least thirty-five feet behind the monitor site. Immediately prior to extraction the arch supports in the extraction zone are removed and then the high pressure jet is directed to the up dip side of the sub-level. Cutting continues until connection is made with the previous extraction area and then the whole of the 70 x 40 foot block is extracted. This allows a completion of the ventilation circuit from the main entry, up the sub-level and out through the gob. Usually a degree of roof caving occurs before extraction is complete, but rock dilution due to this is rarely more than ten percent. After extraction is completed, the equipment is retreated forty feet down the sub-level. The pipe range is recoupled, the flume line reassembled to the feeder-breaker,

eight arches are withdrawn and the process of extraction is repeated. Three sub-levels are equipped at any one time. One is mined, one is pulling back and the third is standing by in case of any unforeseen stoppages in the production sublevels.

When a sub-level is retreated to a point not less than sixty feet from the main road, the equipment is withdrawn for re-installation in another sub-level. A temporary stopping is erected to prevent ventilation leakage. This sixty foot pillar is extracted by a monitor retreating down the main road. The temporary stoppings are destroyed as the pillar is mined but ventilation leakage is prevented as an extraction area is completed by erecting a permanent stopping in the main entry and leaving a barrier pillar.

The caving characteristics of the roof rock at the Michel colliery have not been published so an estimate of the cave line of the hanging wall for the model was obtained from analytically established criteria.¹¹ This analysis provided an angle of break chart which can be used to estimate the angle of break, ψ_b , given the depth of the excavation, depth of caved material, the density of the hanging wall rock, the cohesive strength of the hanging wall rock and its internal friction angle, (Figs.3 and 4). Using this chart ψ_b was determined to be 68° and this value was used in the mathematical model.

Having assumed the likely geological conditions and the general mining method that will be present in extraction of

a hypothetical foothills or mountain pitching seam it was possible to create an idealised section for model analysis. This cross section is illustrated in Figure 5. It assumed that mining has progressed to a depth of 150 metres and that the resulting void has been filled by caved material from the hanging wall. The coal seam was assumed to be fourteen metres in thickness and to have an inclination of 45°. The ground surface was assumed to be level. The hanging wall was assumed to consist of competent sandstone which caves at the break angle described above. The footwall was also idealised as massive sandstone with the same properties as the hanging wall. The idealisation of the country rock as sandstone was considered to be reasonable since sandstones, and high strength siltstones, are common rock types in the foothills coal bearing formations. A description of the deformational properties of several samples of the rocks follows in section 2.3.

2.3 Geotechnical

The strength and deformational characteristics of coal and adjacent strata were based on tests on samples obtained from the Belcourt property in the northeast coal block of British Columbia, and the Grande Cache Mine in the Alberta Foothills. The former is a joint venture managed by Denison Mines Limited's Coal Division and Gulf Canada Resources Inc. and the results are published with their permission. The locations of the two sample sites are illustrated in Figure

6. The samples consisted of 60 millimetre diameter diamond drill cores between 30 and 50 centimetres in length. Each sample was wrapped in plastic film and then coated with wax. This treatment was designed to retain the natural moisture and protect the sample. Uniaxial and triaxial compression tests were then performed on a number of samples in the Department of Mineral Engineering's Rock Mechanics Laboratory.

2.3.1 Uniaxial Tests

Uniaxial tests were performed to determine unconfined compressive strength, Young's Modulus and Poisson's ratio. Five core samples were taken and cut so that their length to diameter ratio was approximately two to one. The ends of these samples were then lapped on a lapping table so that their surface smoothness varied by no more than 0.050 millimetres. Four electrical resistance strain gauges were attached to the sample, two axially and two laterally, using epoxy resin adhesive, in the standard manner. A slow curing adhesive was used without heating to accelerate the hardening process, because it was feared that heat may have caused clay-bearing samples to disintegrate. Each pair of strain gauges was connected to provide a full bridge circuit in a strain meter so that the strain under loading could be determined in microstrain units. The sample was placed in a servo controlled, 600,000 lb. MTS compression frame and loading commenced at a rate of 0.10 millimetres per minute

for stronger materials and half that rate for weaker materials. Strain and load measurements were taken at regular intervals until the sample failed.

2.3.2 Triaxial Tests

Triaxial tests were performed to determine the cohesion and internal friction of the samples. Samples 32 millimetres in diameter were cored from the 60 millimetre diameter diamond drill cores so that their length to diameter ratio was approximately two to one. The ends were lapped in the same way as the uniaxial samples. Each sample was tested in a Hoek-Franklin triaxial cell. It consists of a thick walled cylinder and two end caps. The rock core is enclosed in a tough rubber sleeve which is so designed that when hydraulic fluid is pumped into the cell, the sleeve self-seals and no fluid escapes. The axial load is provided by the MTS compression frame. Each sample type was tested at various confining pressures and the axial failure load for each confining pressure recorded.

2.3.3 Test Results

The uniaxial and triaxial test results are contained in Appendix 1. Values of Young's Modulus were obtained from graphs of axial load against axial strain. Straight line plots were obtained in each case suggesting linear elastic behaviour along the axis. Values varied from 2.55×10^4 MPa for claystones and siltstones to 6.18×10^4 MPa for

sandstones. The results are summarised in Table 3.

Poisson's ratio for each uniaxial sample was obtained from a plot of lateral strain against axial strain. In the higher strength sandstones a straight line was obtained and only one value of Poisson's ratio recorded. In the softer rock materials non-linear behaviour was encountered at high stress levels as failure approached. The value of Poisson's ratio selected was that occurring in the linear portion of the plot. These results are also summarised in Table 3.

The triaxial results were examined using Mohr circle diagrams to obtain values of internal angle of friction and cohesion. The coarse sandstones gave the highest internal friction angle and the silty claystones the lowest. The cohesive strength was low in all cases. The results are contained in Appendix 1 and are summarised in Table 4.

The coal physical property data was obtained from tests on samples from the No. 4 and the No. 11 seam at Grande Cache, Alberta. Uniaxial and triaxial tests were performed and the data is summarised in Table 5. Preparation of coal samples for testing is usually difficult due to its low inherent strength and the presence of many fractures. Therefore the samples which survive the preparation process are usually representative of higher strength and more brittle coal types. For this reason it was possible to obtain elastic constants for coal although the mechanical behaviour across the whole seam may be other than linear elastic.

The mechanical properties of the rock materials obtained from these tests were used in the finite element model. The program employs linear elastic analysis and the predominant rock type, sandstone, exhibits this behaviour. However it has been seen that coal and soft rock materials exhibit behaviour other than linear elastic at higher stress levels.²⁴ The aim of the analysis is not to predict precise stress levels or deformations around excavations but to identify regions in which stress concentrations will occur and support problems may be encountered. Therefore approximating all the rock behaviour as linear elastic is considered justified because the errors introduced by this assumption will be small.

2.4 Pre-Mining Stress Distribution

The factors influencing mine design that have been considered so far are the materials present, their properties, and methods of obtaining coal production. The fourth factor that must be considered when designing excavations is the pre-mining stress distribution, including the effect of tectonic forces. Many investigators throughout the world have measured in-situ lateral and vertical stresses and calculated K_0 , the ratio between lateral and vertical stress.¹² Values vary from 0.4 to over 5.0 and depend on the mechanical properties of the rock and the tectonic history. In the Rocky Mountain Foothills region no in-situ stress measurements have been published to date so

assumption of a value of K_0 should be based on what is known of the tectonic history. The tectonic disturbance seen in the Foothills region is a result of lateral thrusting along a NE-SW axis. This is responsible for the numerous southwest dipping thrust faults found to the east of the Rocky Mountain Trench. This would indicate that lateral tectonic stresses may be significantly high. However Heim's Rule suggests that in weak strata, such as coal bearing strata, the rock is unable to support large stress differences and that in conjunction with time dependent deformation of the rock mass over geological time lateral and vertical stress may equalise. Furthermore erosional effects may enhance this lateral stress release. Therefore some criterion has to be adopted for evaluating a horizontal to vertical stress ratio and it was decided to use the approach of Terzaghi and Richart.¹³ This leads to a value for K_0 of 0.33 which is the value widely adopted for theoretical calculations of pre-mining stress fields. This may appear to be on the low side considering the tectonic history of the region but since no data was available to indicate otherwise the above approach was adopted.

3. Method of Numerical Analysis

3.1 Introduction

The aim of the proposed numerical analysis was to provide a semi-quantitative assessment of the stress distribution around various excavation configurations. To obtain this a two dimensional linear elastic finite element analysis was performed and the results are displayed in two forms. The first consists of contour plots of horizontal and vertical stress distributions. These were produced from the stress values calculated at the nodal points and contoured using the program SURFACE II available in the University of Alberta, Computing Library files. The second form of display consists of major and minor principal stresses represented in magnitude and direction by arrows. The length of the arrow is proportional to the magnitude of the principal stress and its inclination indicates the direction in which it acts. The arrowheads indicate whether the point is in compression or tension; pointing towards each other represents compression and the reverse represents tension. The principal stress plotting program, PLOTGRID, was made available by its author Mr. P. Weerenburg of the University of Alberta, Department of Civil Engineering.

3.2 The Finite Element Program

The main computational program that was employed for the model is a two dimensional finite element program developed in the University of Alberta, Department of Civil Engineering. It performs a two dimensional, linear elastic analysis for plane strain problems using a constant strain triangle and outputs displacements, element stresses, maximum principal stresses and average nodal stresses. For use in this problem it was necessary to increase the program limitations. The maximum number of nodes was increased from 200 to 450, the number of elements from 200 to 900 and the half-bandwidth from 40 to 200. The limitations therefore read as:

Number of Nodes 450

Number of Elements 900

Half Band Width 200

Materials 8

Total Storage Required 720k

The program can be run under the Michigan Terminal System on the AMDAHL 470 V/7 computer at the University of Alberta. The required Central Processing Unit (CPU) time is approximately 45 seconds.

3.3 The Element Mesh and Element Properties

The finite element mesh is illustrated in Figure 7. It has 432 nodal points and 812 elements with a high concentration in the seam and in the immediate hangingwall and footwall. The elements in the seam are so arranged that different mining configurations can be modelled with this mesh by assigning different element material properties and loading conditions without having to change nodal coordinates or element nodal points. Also a high number of elements are placed on the coal/sandstone interface in the region of the excavations. This is to prevent displacements in the coal being overly restrained by the relatively stiff sandstone since the ratio of elastic moduli, coal to sandstone, is 1 to 20.

The elastic properties used for elements representing coal and sandstone were those established in the materials testing program (Chapter 2). For excavated zones such as the working-places and the sublevels the elements were assigned near zero stiffness i.e. the value used for Young's Modulus was 10.0 MPa and that for Poisson's ratio 0.25. These values are selected to allow deformation into these regions to occur readily. The caved sandstone was assigned a Young's Modulus of 1200.0 MPa and Poisson's ratio of 0.25. No specific values were available for this material so the moduli ratio of coal to caved sandstone was chosen as 2 to 1. For solid rock the Young's Modulus value used was 50,000 MPa and the Poisson's ratio 0.2. This was an average

obtained from the testing program summarised in Table 3. The values for coal were 2400 and 0.35 respectively. These values were gained from the coal physical property tests summarised in Table 5.

The use of linear elastic analysis for this problem may be considered an over simplification especially since more complex analyses can be performed. The most advanced method currently available for calculating stresses in a problem of this nature is by means of a finite element method using incremental loading to simulate the mining history and non-linear, stress path dependent stress-strain relations for the materials involved. With proper use this procedure has been shown to lead to reliable estimates of the stress distribution as well as the deformations resulting from a given loading sequence. However, it has been shown²³ that if deformations are not required, then for many cases a simple linear elastic, single step analysis may give satisfactory results with less expenditure of time and money.

3.4 Initial Stress Distribution and Boundary Conditions

The initial vertical stress was assumed to be due to the weight of overlying material. Therefore the vertical stress at a point z metres below the surface is given by

$$\sigma_v = \gamma \cdot z$$

where γ is the unit weight of the material.

If a point occurred below more than one material the vertical stress value was calculated as $\sigma_v = \gamma_1 \cdot z_1 + \gamma_2 \cdot z_2 + \dots$

The unit weights for coal, sandstone and caved sandstone were 1300, 2700 and 1890 kg/m³ respectively.

The initial horizontal stress distribution was calculated from

$$\sigma_h = K_0 \sigma_v$$

where K_0 is the value of the horizontal to vertical stress ratio established in Chapter 2. The initial horizontal and vertical stress distributions are illustrated in Figures 9 and 10. The axes indicate distances in metres and the contour values represent stresses in Mega-Pascals.

The initial stress distribution could have been calculated using the "switch on gravity" method. This is achieved by running the finite element program with the self weight of each element being applied. The advantage of this approach is that shear stresses developed along boundaries where materials possess different stiffnesses are simulated. However away from the boundaries the horizontal to vertical stress ratio will be that arising due to the elastic properties of the materials and will give a similar initial stress distribution to that obtained by the calculation described in the preceeding paragraph.

The element mesh boundary conditions were defined such that the nodes on the boundary were fixed in both the horizontal and vertical directions. The mesh is sufficiently large that boundary conditions do not influence behaviour around the excavations.

4. Stress Analysis of Sublevel Mining Configurations

4.1 Introduction

The particular panel layout in a sublevel mine may change from panel to panel to allow for geological variations or to improve strata control. For this reason it was decided to analyse four alternative panel layouts by the method previously described. For each layout a section and plan describe the extraction method and another section describes the loading conditions in the region of the excavations. Stress contours and principal stress diagrams illustrate the results.

4.2 Loading Conditions

The method of calculating the excavation loading conditions was the same for each configuration. The stress at each nodal point on the boundary of the excavation was obtained from the listing of initial stress distribution. These values were used to calculate loads which are applied at each node along the excavation boundary to create a stress free boundary around the excavation (Figure 12). A sample calculation of loading conditions is given in Appendix III. The induced stress distribution caused by this loading and calculated by the finite element program is summed with the initial stress distribution to give the final stress distribution around the excavation.

4.3 Configuration 1

4.3.1 Extraction Method

Coal blocks due for extraction were assumed to be bounded by development sublevels turned off the main entry almost parallel to strike. They are retreated back towards the main entry by hydraulic extraction and all roads are sufficiently inclined to allow hydraulic transportation of the broken coal. Coal on the down dip side of the extraction sublevel is trimmed off so that the coal wall is perpendicular to the roof. The layout and dimensions are illustrated in Figure 11.

4.3.2 Final Stress Distribution Throughout the Structure

The horizontal and vertical stress distributions resulting from this configuration are illustrated in Figures 13 and 14. In comparison with the initial stress distribution diagram (Figure 9) it can be seen that there is a certain reduction in horizontal stress in the footwall and a slight increase in the hanging wall. Also a zone of horizontal tensile stress is induced near the surface which coincides with what would be the location of the new cave line. A high horizontal stress gradient is seen in the hanging wall sandstone as it approaches the sandstone/coal interface in the region of the excavations.

The vertical stress distribution is characterised by a slight lowering of stress magnitude in the footwall and a slight increase in the hanging wall. As would be expected

variations from the initial stress levels increase closer to the excavation. The vertical stress along the boundary between the intact and the caved sandstone is low because displacement of the intact rock into the stope allows stress release.

The principal stress distribution diagram (Figure 15) adds more to the detail provided by the horizontal and vertical stress diagrams. The development of the new cave line is illustrated by the major principal stress near the surface being horizontal and tensile. Also it can be seen that in the hanging wall the major principal stress is oriented parallel to the seam and is large and compressive. Its significance will be discussed in the next section.

4.3.3 Final Stress Distribution Around the Excavations

The stress distributions are illustrated in Figures 16, 17 and 18 and stress sections through regions of particular interest are contained in Figures 19 to 22. It should be noted that the stress levels indicated by these sections are those occurring along each straight section line. Figure 19 shows that the horizontal stress in the immediate hanging wall is almost constant parallel to the seam from the uncaved stope to below the next working drift. This is contrary to the initial stress distribution where the horizontal component increases linearly with depth and, for a given depth, is lower. A similar section in the footwall shows that stresses increase with depth except immediately

below the uncaved stope. Stress sections perpendicular to the seam (Figure 20) show high horizontal stress in the hanging wall dropping abruptly in the coal, reaching a minimum in the excavation wall on the footwall side and rising slowly in the sandstone footwall. This distribution is partly a result of the initial condition where footwall stresses are low because the loading provided by the less-dense caved material is lower than that of the intact rock which loads a large part of the hanging wall. Another factor causing this particular stress redistribution is stress transfer around the openings. The horizontal component is transferred below the lower excavation and through the pillar between the two excavations. Also the vertical component is forced around the excavation in the sandstone hanging wall and the major principal stress becomes oriented parallel to the seam (Figure 18) This adds a further component to the already increased horizontal component.

In the footwall the horizontal stresses are considerably lower than in the hanging wall. Destressing occurs in the immediate floor of the stope and in the walls of the development drift. The orientations of the major principal stresses are much nearer to their original orientations (i.e. vertical) except for immediately below the stope where they tend to the horizontal. This results in a local horizontal stress concentration which is, however, relatively small.

The vertical stress distribution is characterised by high hanging wall stress, moderately high pillar stress, high stresses in the walls of the development drifts, and localised zones of stress concentration and relaxation. Low stress in the footwall is partly a result of the reduced overburden load caused by the caved material but also due to relaxation immediately below the stope.

As has already been noted the major principal stresses in the region of the stope become aligned parallel to the roof and floor. Figure 18 illustrates the manner in which stress is transferred around the end of the stope and this causes a vertical stress concentration in the sandstone hanging wall in the region of the top corner of the stope. In the footwall there is a destressed zone in the sandstone below the stope. This appears to be caused by relaxation in that bottom corner and also because there is no transfer of stress through the region. This gives a high differential stress across the end of the stope which is well illustrated in the upper section in Figure 22.

In the pillar section between the two excavations stress transfer gives rise to a moderate increase in stress level with a subsequent drop in stresses in the footwall. The footwall stresses in this zone tend to be similar in magnitude and orientation to the initial stresses. Around the lower excavation vertical stress is predictably transferred around the drift leading to high stress in the walls and destressing in the roof and floor. The area

influenced by the excavation continues for at least 75 metres below the lower excavation giving higher stresses in the hanging wall but not significantly affecting stress distribution in the footwall. This suggests that overburden load from the overlying rock is transferred around the excavation as a whole and will always lead to a zone of increased stress in the hanging wall at depths in which further development workings will have been initiated.

4.3.4 Significance of Observed Stress Distribution

The analysis of this configuration can give some initial insight into possible ground behaviour around an uncaved stope. The major principal stress in the stope roof is compressive and aligned parallel to the seam so this will have the effect of closing any joints in the roof and preventing failure by sliding of unsupported blocks. The localised tensile zone where the stope roof joins the previously caved material suggests where roof failure will be initiated and its continuation through to the surface locates the new cave line.

The horizontal and vertical stress concentrations located in the hanging wall may cause stability problems on the corner at the junction between the sandstone roof and the coal wall. High compressive stresses are created in the coal wall and may cause its failure which would remove support from the roof. This could in turn induce the failure of the hanging wall. The eventual caving of the hanging wall

is of course desired but not at the expense of depletion of recoverable coal from the adjacent coal block.

The overall destressing of the footwall will be significant in the location of permanent excavations such as major haulages, slurry pumping stations and shafts. As the workings go to greater depths shafts will have to be deepened or subshafts added and these will all be located in the footwall to take advantage of the destressed and more stable ground.

4.4 Configuration 2

4.4.1 Extraction Method

The extraction method for this configuration is similar to the previous one but a number of changes are embodied which will affect the resulting stress distributions. As before extraction blocks are defined by continuous miners and production is achieved by retreat hydraulic mining back towards the main entry. No trimming is performed on the down-dip side so the resulting stope retains the original profile of the extraction sublevel. Furthermore the pillar between the stope and the lower sublevel is of lesser volume in this configuration which should also affect the final stress distribution. The mining layout is illustrated in plan and section in Figure 23.

4.4.2 Loading Conditions

The loading conditions for this configuration are calculated as before and are illustrated in Figure 24.

4.4.3 Final Stress Distribution Throughout the Structure

The overall stress distribution is illustrated in Figures 25, 26 and 27. The horizontal stress distribution is similar to that of Configuration 1 but the change in geometry does create some differences. The tensile zone near the surface is still present but is not so extensive. This suggests that the new cave line will be propagated in the same location but may not occur so readily. The release of horizontal stress in the footwall is as in the previous mining layout with a slightly lower level of horizontal stress below the pillar. As before the initial stress distribution is significant in determining the footwall stress condition.

Predictably, the vertical stress distribution across the mesh varies little from that of the previous configuration. The destressing along the boundary between intact and caved sandstone is still observed as is the considerable relaxation in the footwall below the stope. The principal stress diagram (Figure 27) shows the orientation of the major principal stress in the stope roof parallel to the seam and shows a transfer of stress around the excavation as a whole.

4.4.4 Final Stress Distribution Around the Excavations

The small variation in geometry and pillar size in this configuration results in a change in horizontal stress distribution around the excavations. The stress section in the hanging wall parallel to the seam (Figure 31) shows an almost linear increase in stress with depth, a sharp drop as the lower excavation is encountered, and then a resumption of the linear increase with depth. The drop in stress coincides with the location of the destressed vertical wall of the lower sublevel. The equivalent stress section in the footwall shows stress decreasing to a minimum below the stope, rising as the pillar is encountered but remaining constant through the footwall of the pillar, increasing rapidly below the lower sublevel, and then showing a gentle linear increase with depth below the excavation zone. Stress sections perpendicular to the seam show horizontal stress levels rising in the hanging wall to a peak on the interface between coal and sandstone, dropping sharply and remaining constant or increasing slowly in the footwall.

The most significant horizontal stress concentration induced by the excavations is in the hanging wall sandstone adjacent to the coal pillar (Figure 28). As before this is a result of horizontal stress transfer around the openings and the reorientation of the major principal stress. The major principal stress becomes oriented parallel to the seam and thus adds to the horizontal component. Stress relaxation in the footwall is slightly more extensive and more uniform

than in the previous configuration.

Vertical stress in the hanging wall rises rapidly from almost zero to peak in the sandstone adjacent to the vertical wall of the stope. It then falls to an intermediate minimum above the roof of the lower sublevel, rises to the original peak in the wall of the sublevel and stays at this value until it is well below (60 metres) the lower excavation. In the footwall vertical stress decreases almost linearly until it reaches a minimum below the bottom corner of the stope. From there it rises sharply through the pillar region to a peak which coincides with the wall of the sublevel. Below the sublevel considerable destressing is observed and then a sharp increase in stress in the vertical wall on the down-dip side. From that point on stress increases linearly with depth to achieve levels similar to those present in the initial stress distribution. Across the seam (Figure 34) stress rises to a peak in the hanging wall, falls sharply around the excavation and recovers slowly in the footwall. In the pillar region stress increases to a maximum in the centre of the pillar, decreases in the footwall then assumes initial values and increases linearly with depth.

The most significant vertical stress concentrations occur in the lower sublevel walls and in the single vertical wall of the stope. Relaxation is seen above and below both excavations. The stress gradient across the seam and the magnitude of the peak stresses are slightly lower in this

configuration than the previous one. The variation in stope geometry has only had a minor effect on vertical stress distribution. The principal stress diagram illustrates stress transfer through the pillar and around the excavations as a whole. The tensile zone in the roof of the stope where bed separation may occur and roof caving will be initiated. Below the excavation zone initial stress conditions are soon regained as can be seen from the way in which the principal stresses return to being vertical and horizontal.

4.4.5 Significance of Observed Stress Distribution

As in the previous configuration the compressive major principal stress aligned parallel to the stope roof will add to its stability by closing joints perpendicular to bedding. Similarly further development in terms of access should be located in the footwall sandstone to take advantage of the destressed and more stable conditions. Since no trimming is performed on the down-dip side of the sublevel the bottom of the stope retains the sublevel profile. On comparison of the principal stress diagrams of these first two configurations (Figures 18 and 30) it appears that Configuration 2 is more desirable because of the way in which stress is distributed around the lower end. In Configuration 1 the magnitude of the major principal stress at several points is higher than in Configuration 2. Also in Configuration 2 the highest stresses are in the sandstone and located further from the

coal than in Configuration 1 thus reducing the risk of premature caving and coal loss. The differences pointed out here are, however, marginal and the stability could be affected by other factors such as the presence of soft coal or poor roof conditions. As a result a choice between these two mining configurations would be based on factors such as productivity and ease of mining rather than the optimisation of stability by consideration of stress distribution.

4.5 Configuration 3

4.5.1 Extraction Method

The third layout to be considered embodies the broad sub-panel layout as practiced in some Chinese hydraulic mines (Chapter 5). Extraction blocks are smaller and are subdivided by crosscuts (Figure 35) to improve access and ventilation. Development work is carried out with continuous miners and bulk production is achieved by hydraulic retreating towards the main entry. With this layout more than one block is extracted simultaneously to offset the lower production rate caused by mining smaller blocks. Flumes for coal slurry transportation are located in the production sublevels and the main entry.

4.5.2 Loading Conditions

The loading conditions for the chosen section through the workings (Figure 35) are illustrated in Figure 36. These are calculated as described earlier and as can be seen from

the diagram result in a fairly simple configuration to be analysed.

4.5.3 Final Stress Distribution Throughout the Structure

The selected section through the mine workings is such that stresses around three sublevels are analysed so in relation to the rest of the structure, the actual volume of unexcavated rock is small. This is seen in Figures 37, 38 and 39 where away from the excavations the alteration from the initial stress distribution is minimal. There is a slight rise in horizontal stress in the hanging wall in the region of the excavations and this is due to transfer of stress through the solid coal pillars. In the footwall, where away from the excavation the stress level rises linearly with depth, the stress distribution becomes almost identical to that of the initial stress. The tensile zone at the surface is very low in magnitude and small in extent and would be unlikely to promote any caving.

The overall vertical stress distribution diagram emphasises that away from the excavation there is little variation from initial conditions. Above the uppermost sublevel there is a certain relaxation of stress along the boundary between the caved and the intact sandstone but not as significant as that observed above the stope in the two previous configurations. There is also a slight destressing in the hanging wall above the excavations and a stress increase in the hanging wall below the excavation. Vertical

stress has been transferred around the excavation zone as can be seen from the major principal stress trajectories in Figure 39.

4.5.4 Final Stress Distribution Around the Excavations

Stress sections parallel to the seam show a steady increase in horizontal stress with depth in the hanging wall, with a small peak adjacent to each pillar caused by local transfer of stress around each sublevel (Figure 43). In the footwall the stress level is more or less constant until below the bottom sublevel. A sharp increase here is due to the overall stress transfer around the excavation zone. Sections perpendicular to the seam illustrate the destressing in the sublevel walls and the subsequent concentration in the floor.

Vertical stress sections illustrate a similar pattern of relaxation and concentration in the hanging wall and footwall. The general trend is for stress magnitude to increase with depth and there are local peaks where vertical stress is channelled through a pillar. The peaks actually occur in the sublevel walls but the stress levels in the pillars are still higher than those occurring prior to extraction. The principal stress diagram illustrates the stress trajectories around the excavations. It also illustrates an anomaly in the roof and floor of the excavations caused by the way in which stresses are calculated at nodes. Stresses at nodes (which are contoured

here) are calculated by averaging of the stresses in the elements surrounding the node. On the boundary of the excavations stresses are therefore averaged between the elements at zero in the excavation and the stressed elements in the surrounding rock. Above and below the excavations, vertical destressing has occurred but the magnitude of the average vertical stress is still greater than the horizontal stress. This results in the inaccurate representation of the major principal stress on the excavation boundary.

4.5.5 Significance of Observed Stress Distribution

Since the section analysed passes through consecutive pillars and sublevels and does not include any large unsupported excavations, the structure appears fairly stable. This will be misleading as each block is retreated because as the excavation front approaches the section line, stress variations will arise in the third dimension. Such an effect is, however, beyond the scope of this investigation. There appear to be no real problem areas created by this excavation configuration but two points should be noted. The concentration of vertical stress in the sublevel walls may result in their failure especially as operations proceed to greater working depths. This will require increasingly stronger support to be set immediately after excavation as is the practice in some hydraulic mines (Chapter 5). The second point is that as the pillars are stressed they may become more liable to violent failure or outbursts of

powdered coal and gas.

4.6 Configuration 4

4.6.1 Extraction Method

The layout illustrated in Figure 47 and analysed as Configuration 4 is typical of the method of long pillar mining or narrow sub-panel mining (Chapter 5). Unlike the three previous methods the direction of excavation is almost down-dip as opposed to being just off strike. As before the extraction blocks are defined by continuous miners and are then retreated towards a cut-off drift. In this method the coal slurry runs down the production sublevels, along the cut-off drift and into the main entry.

4.6.2 Loading Conditions

Nodal loadings to simulate the desired excavations are calculated as before and illustrated in Figure 48.

4.6.3 Final Stress Distribution Throughout the Structure

Figure 49 illustrates the general horizontal stress distribution and it can be seen that apart from local alterations around the excavations and a slight destressing in the footwall, there is little alteration from the initial stress distribution. At the surface there is a small tensile zone but its magnitude and extent are not sufficient to give rise to instability. The same is true with regard to vertical stress distribution. Localised effects are seen around the

excavations and some vertical stress is released in the footwall, but generally the stress distribution is the same as that prior to excavation.

4.6.4 Stress Distribution Around the Excavations

In the hangingwall the magnitude of horizontal stress rises with depth and attains a peak above the lower sublevel. It then falls above the sublevel wall but recovers its peak value and continues to rise linearly with depth. In the footwall a similar situation occurs with minimum levels below the sublevel walls and magnitude increasing with depth. Stress sections across the seam reiterate this pattern and the section through the coal pillar shows only a marginal concentration in this region.

The vertical stress sections show almost constant stress between the two excavations parallel to the seam, with destressing above each sublevel and stress concentration in the sublevel walls. In the footwall the relaxation and concentration occurs as in the hanging wall, but between the sublevels stress magnitude increases with depth as it would prior to mining. Sections across the seam show a slight increase of stress level in the central pillar and the predictable concentration in the excavation walls. The principal stress diagram shows the principal stress trajectories and the stress transfer around the sublevels.

4.6.5 Significance of Observed Stress Distribution

As was observed in the previous configuration there are no severe problems created by the stress redistribution around the sublevels. Concentration in the walls can be alleviated by suitable support and there should be little danger of outbursting in the pillar zone because the magnitude of the induced stresses rarely exceeds the initial stress levels. The pillar adjacent to that between the sublevels (the pillar being extracted, Figure 47) will no longer support overburden load and will transfer stress to the caved material and the pillar which has been considered here. This will increase the stress level in this pillar but an assessment of the influence of this stress transfer would have to be performed by three dimensional analysis which lies beyond the scope of this project.

5. Comparison of Theoretical Results with Mine Observations

5.1 Introduction

In order to validate the results from the mathematical model analysis it was decided to compare them with reports of observations made at three mines operating with similar configurations. In China, hydraulic mines have been operated for approximately thirty years and some of their strata control problems have been described.¹⁴ In the Michel colliery of Kaiser Resources (Chapter 2) deformation and convergence measurements were performed and their significance evaluated.¹⁵ Finally in Zambia, at the Mindola Mine, a steeply dipping, low strength copper orebody is extracted by sublevel methods and its similarity in mine structure allows useful comparisons to be made.¹⁶ Unfortunately, none of these descriptions quantify stress magnitudes and they provide only qualitative observations. Since so few studies have been made in steep seam operations these observations can only be used in general comparison.

5.2 Observations in Chinese Hydraulic Mines

Since the inception of observations in 1956 the Chinese have been investigating roof stability in the workings, deformation in the extraction blocks under pressure, and roadway maintenance. They conclude that the behaviour of the immediate hanging wall strata (main roof) plays a predominant role in deformation in coal blocks and the

damage incurred in roadways. If the hanging wall fails to cave stress is transferred to the coal causing crushing of coal pillars, increasing the unsupported roof span, and extending the area affected. Problems are more acute in areas of high productivity and high methane content.

At the Hsiechiachi No.3 Colliery in working a 5.6 metre thick seam, dipping at 23° and at a depth of 250 to 500 metres, it was found that loading on roadways caused severe deformation and maintenance problems. It was decided therefore to locate main entries in the footwall strata and plan production so that required roadway life was minimised. Development of a panel adjacent to the panel under extraction is only commenced when extraction of the first panel is near completion. By fast drilage techniques the sublevel is completed in five days and the resulting panel extracted in ten days. An average production rate of 200 tonnes per hour yields a daily production, from each panel, of 2000 tonnes. This is equivalent to a doubled output per man shift (OMS) and is accompanied by a 60 percent drop in timber consumption compared with former methods. The success of this method is due to the reduction of roadway life and the fact that roof caving has been initiated before the next roadway is started. By the time the roadway is completed and the new panel commences extraction, the roof has caved and the broken rock can support overlying strata thus relieving the coal pillars of some of their load.

A second technique to improve working conditions

adopted by the Chinese was to change the panel layout from broad sub-panel to narrow sub-panel. The former is equivalent to Configuration 3 and the latter to Configuration 4 in the model analysis (Chapter 4). It was found that by using this technique stress was transferred to adjacent undeveloped panels which were capable of bearing stress without crushing, until the hanging wall caved. When development was due in these panels it was found that the roadways remained in proper shape and a significant improvement was obtained in production.

Other experiments performed at several other collieries related to increasing support in roadways to prevent closure. Timber sets comprising a cross-bar and three props were employed as were yielding steel arches. Also the spacing between supports was reduced to obtain maximum stability. Drivage by drilling and blasting was replaced by continuous miners to keep roadway wall damage to a minimum and wooden bolting was used to stabilise the sides. Better production planning reduced roadway service time and the overall benefits of these measures made the increase in support costs acceptable.

Many of the conclusions reached by the Chinese engineers by mine observations and "trial and error" can be reliably inferred from the mathematical model analysis. The various studies suggested that high stresses will be found in coal pillars and roadway walls and that their distribution and magnitude is related to the span of

unsupported stopes and roadway spacing. By locating main entries in the footwall strata (Hsiechiachi Colliery) they took advantage of the distressed zones observed in all the mathematically analysed configurations. In changing from broad sub-panel layout to narrow sub-panel layout induced stresses in the pillars were reduced and this is seen by comparison of Configurations 3 and 4. These observations suggest that on a comparative basis the mathematical model is fairly reliable for predicting the location of problem zones and show how the layout can be altered to achieve maximum stability.

5.3 Observations at the Kaiser Resources Hydraulic Mine

Operations at the Michel Colliery have been described in Chapter 2 and are similar to the Chinese operations in layout and method of working. Strata control studies were initiated at this mine to assist in planning for production at deeper levels and in the layout of a new mine.¹⁵ The research program was designed to establish support loads in sublevels, the magnitude of pillar deformations, the amount of strata movement above and below the sublevel and the amount of convergence in the sublevel.

The support loads measured on arches located in a production sublevel gave maximum loads of 11 tonnes. This figure is difficult to relate to local stress conditions since the size and spacing of the steel arch supports is not specified. However, it was noted that arches rarely reached

yield load which indicates that either loading in the sublevel is not severe or the sublevel is over supported. Roof convergence was measured along the sublevel as the block was retreated and the maximum value of 60 millimetres was achieved at the measuring point closest to the monitor. Further back down the sublevel convergence was found to be smaller. Strata movements measured by multi-wire extensometers indicated a roof lowering of 17.3 millimetres at a point 36 metres above the sublevel and an uplift of 21.5 millimetres at a depth 6 metres below the sublevel. These measurements corresponded well with the total roadway closure which at the same point was 45 millimetres. Pillar deformation measurements showed maxima occurring at some distance back from the extraction face. In the sublevel the maximum deformation of 18.5 millimetres occurred when the monitor was 76 metres away from the station. This suggests a stress transfer mechanism that induces a maximum loading some distance back from the extraction face.

Relating these results to the mathematical model analysis is difficult because the two types of data obtained cannot be readily compared. The researchers expressed surprise that the convergences and deformations were so small and also that the area of influence tended to be very much greater than would be expected from a conventional mining area within relatively thin seams. The principal stress diagrams generated by the mathematical model (Chapter 4) show that the area of influence of the excavation on the

stress distribution is considerable (in excess of 50 metres from the excavation). However no other conclusions can be readily drawn as to similarities between the two analyses.

5.4 Observations at the Mindola Mine

The sublevel mining system at the Mindola Mine is very different from the two mines previously described because it is a hard rock operation operating at depths of 650 to 1000 metres. However the sublevel layout and the dip of the orebody are similar and the relatively weak ore bounded by hard quartzite country rock can be likened to the coal seams contained in the strong sandstones of the Foothills formations.

A number of observations were made in this mine to discover highly stressed zones, and modifications to the mining system were adopted to alleviate severe problems. It was noted that above the extracted stope the hanging wall roof beam would sag but fail to cave. Eventual failure of this layer produces a violent air blast that effects the safety of working places. This observation concurs with the mathematical model analysis where in Configurations 1 and 2 the alignment of major principal stress trajectories parallel to the stope roof may be responsible for its reluctance to fail. It was further observed at the Mindola Mine that stresses peaked in the hanging wall and footwall of the pillar immediately below the uncaved stope. This is also seen in the mathematical model where stress transfer

mechanisms seem to be similar.

A major problem noted at the Mindola Mine related to blast holes drilled from a sublevel into the extraction block above. All production was achieved by drill and blast techniques as opposed to hydraulic breakage and this required long blastholes to be drilled in rings around a production sublevel. As depths increased it was noted that long holes deviated or closed soon after drilling. To make the long holes functional they had to be charged immediately after drilling although they would not necessarily be blasted for two or three weeks. The high pressures and the ground movements in these blocks promoted premature detonation of some holes and this occurred more frequently at greater depths.

This problem is demonstrated in the mathematical analysis where, especially in Configurations 1 and 2, high pillar stresses occurred. The significance to a sub-level operation is not of course premature blast hole detonation but crushing of valuable coal in the pillar and perhaps the increased likelihood of coal and gas outbursts. Also greater roadway maintenance may be required.

6. Physical Model Studies in Steep Seam Mining

6.1 Introduction

As an integral part of research into the mining of steeply dipping thick seams physical model studies have been performed by other researchers within the Department of Mineral Engineering.¹⁷ It was considered useful to compare the results of the physical model studies with those of the mathematical analysis. Physical models can provide a qualitative assessment of how an excavation may behave under gravity loading and suggest the location and nature of deformations. The base friction technique employed in these studies has been available for approximately ten years and has been modified and improved upon by various investigators in that period.^{18 19} In this chapter the modified base friction technique is described and the results are compared with those obtained from the mathematical analysis performed by the author.

6.2 Model Materials

For effective physical modelling model materials must be chosen such that their properties relate to those of the in-situ strata. This is achieved by selecting materials whose compressive strength is at a constant factor lower than the compressive strength of the rock material but has similar stress-strain relationships. Two model materials were selected for simulation of coal and sandstone and their

properties are briefly described below.

6.2.1 Coal

Coal is modelled by a mixture of plaster, sand and vermiculite. It is compacted in layers to simulate bedding and the mixed vermiculite grains give a cleat texture to the model material. It is a low density material (1114 - 1282 kg/cu.m) and has a low uniaxial compressive strength between 0.05 and 0.1 MPa. The strength scaling factor of the model material to coal is 1:160 for coal samples taken from the No. 4 seam at Grande Cache. The uniaxial strength of this moderately hard coal is between 10.0 and 17.2 MPa. The stress-strain diagrams (Figure 59) of both coal and the model material were found to be sufficiently similar to make this a valid modelling material.

6.2.2 Sandstone

For modelling sandstone a material composed of fine sand and plaster was used. As before it was compacted in layers to simulate bedding. The material has a fine grained texture and a density of 1560 - 1672 kg/cu.m. The model material has a uniaxial compressive strength of 0.58 - 1.03 MPa which when multiplied by the scaling factor of 1:160 falls within the values of sandstone uniaxial strength which are in the range 96 - 200 MPa. The stress-strain behaviour to failure of the model material is similar to sandstone in that they are both linear and exhibit brittle failure

(Figure 60). The axial strain at failure of both the sandstone and its model material is about one quarter of the axial strain at failure of the coal and its model material. Since the strength and strain properties have been scaled uniformly the two materials were considered suitable for modelling.

6.3 Model Frame and Loading Conditions

The base friction frame used was built in the Department of Mineral Engineering and has been described in detail elsewhere.²⁰ It consists of a wooden frame approximately 1.5 metres by 2.5 metres containing a continuous friction belt which is driven by a small electric motor. There is a facility to incline the frame and belt as required (Figure 61). The particular model described here used only the lower portion of the frame since relatively small scale tests were being performed. Another modification adopted by the researchers was similar to that developed by Egger.²¹ He describes a model in which the material is confined in the third dimension (out of the plane of the model) by a sheet of plexiglass which is subsequently loaded by compressed air rams. This has the effect of increasing the normal reaction of the model material on the friction belt which in turn increases the shear stress acting on the model material. In the tests described here the compressed air rams were replaced by lead weights spread evenly across the surface of the plexiglass. Additional loading of the

model material was achieved by two other measures. Firstly the belt was inclined at an angle of 25 degrees so that a gravitational component is added to the shear stress induced by the belt. Secondly lead weights were placed along the top edge of the model material to add a further load component (Figure 61). These measures are taken so that higher strength materials can be used with failure still occurring. When dealing with very low strength modelling materials it has proved difficult to obtain constant material physical properties.

The loading conditions and the structural configuration of the model are illustrated in Figure 62. The model material is confined horizontally and along the bottom edge by rigid barriers to prevent displacement in these directions. The model represents a 45 metre thick coal seam dipping at 30 degrees between two beds of sandstone. Mining is simulated to a depth of 150 metres and three sublevels are excavated in the seam by removing coal material (Figure 63). This layout is therefore similar to that analysed in Configuration 3.

6.4 Operating the Model

On completion of construction of the model, with removal of the appropriate coal material, the confining barriers and plexiglass sheet can be positioned. The lead weights are then placed on the plexiglass and along the top edge, and the frame inclined at 25 degrees. The belt is set

in motion by the motor for a few seconds and then stopped. The effect on the model is examined and the result photographed. A problem was reported at this stage because photography of the model required removal of the lead weights and the plexiglass. This allowed some minor deformation in the direction supposedly confined by the plexiglass. The deformation in this plane was considered to be so small, however, as to be insignificant. The model is reloaded and the cycle repeated until no further deformation is recorded. The deformation stages are photographed and reproduced in photographic plates 1 to 6. However since definition is rather poor the plates have been represented as line drawings in Figures 63 to 68 and these are used in the following section to assess the physical model results.

6.5 Physical Model Results

The nature of the deformations obtained from the physical model tests illustrated in Figures 63 - 68 show reasonable agreement with the observations made in the operating mines and those generated by the mathematical modelling. The results can only be used qualitatively to identify areas of potential instability and modes of failure but the method does provide one of the best visual representations of deformation induced by mining.

6.5.1 Deformation Throughout the Structure

In the extracted zone the initial deformation is considerable and predictable. The immediate roof layers separate along a simulated bedding plane to create a roof beam. This starts to sag and then fails in tension perpendicular to bedding (Figure 64). This failure process is repeated throughout the hanging wall zone to the surface until the void is filled with caved material (Figure 65). The failure of the roof layers with progressive sagging and final failure is similar to that observed in the Chinese hydraulic mines (Chapter 5). Figure 65 illustrates the angle of break generated by the caving of the hanging wall. In this case it is found to be 65 degrees which agrees very closely with the angle used in the mathematical model, 68 degrees, which was derived from Hoek's criteria (Chapter 2). Along this boundary two modes of failure are active. The weight of the unsupported overhang results in a tendency for the hanging wall to try and rotate. This generates tensile forces near the surface which are seen in the mathematical model analysis. This may lead to the development and propagation of tension cracks along the boundary (Figure 69). Shear forces due to the weight of the overhanging wedge may also be active along this boundary and their presence will be more noticeable because of the reduction in normal force caused by the rotational effect.

A second major deformational feature seen in the model occurs approximately 50 metres (scaled) above the pillar

between the first and second sublevels. This feature is bed separation and is the result of closing of sublevels and deformation of pillars in the coal seam. Bed separation was recorded in the Kaiser hydraulic mine (Chapter 5) by multi-wire borehole extensometers at a point 36 metres above the sublevel so a similar occurrence in the physical model is encouraging.

6.5.2 Deformation Around the Sublevels

The deformations around the sublevels and in the pillars photographed in Plates 4, 5 and 6 and illustrated in Figures 66 - 68 are also observable in the operating mines and the mathematical model. High pillar stresses noted in Configurations 1, 2 and 3 have resulted in partial failure of the pillar between the first and second sublevel especially in the footwall. This is evidenced by the cracking and generation of powdered material. This effect was also observed by the Chinese who described pillars of crushed coal which had very low bearing capacity. The displacements in the pillar would also agree with the deviations and deformations of the blast holes noted in the Mindola Mine (Chapter 5).

Instability in the sublevels is also noticeable with the uppermost sublevel experiencing total closure and the middle sublevel showing deformation in the floor and cracking in the roof. This confirms the need for sublevel support as is utilised in all the hydraulic mines studied.

The uppermost sublevel experienced roof closure and floor uplift. Floor uplift or heave is experienced in many coal mines of varying configurations and is a result of stress redistribution below the excavation. Due to stress relief in the floor vertical stresses at the excavation boundary go to zero so that the immediate floor is effectively in uniaxial compression. This leads to compressive failure in the unconfined direction, vertically upwards, and gives rise to floor heave. In many deep coal mines floor heave of up to one metre in two or three days is not uncommon.

Severe disturbance in the sublevels adjacent to the workings was recorded in the Chinese hydraulic mines with lesser effects noted in the lower sublevels. This is also seen in the physical model and in conjunction with the other observations demonstrates its validity for general prediction of unstable zones.

7. Conclusions and Recommendations

This thesis represents a preliminary analysis of some aspects of a mining technique that may be utilised in the extraction of steep seams in the Foothills and Mountain region of Western Canada. It proceeds with little knowledge of the properties of the rocks and coal of the region, and their behaviour under extraction. It indicates that there is a contribution to be made to mine design and planning by modelling techniques. Mining of coal has been practiced around the world for centuries and to a large degree design methods have relied on "rules of thumb" and trial and error techniques. The capital intensive mining developments in the remote areas of the mountain region will require research and planning to reduce the risks and unknowns involved in adopting new mining techniques. The conclusions in this chapter and the resulting recommendations therefore represent the author's opinion of how research should develop so that sublevel hydraulic coal mining can be practiced more efficiently in the future. Although published material on this method of mining is scarce it would appear from experience in China, Russia and the single mine in Western Canada that the sublevel method will see wider utilisation. Certain features increase its safety over conventional methods namely the elimination of explosives, the dust suppression provided by the cutting and transport media, and the removal of the requirement for men to enter the actual working area. Accepting, therefore, that this

method will be employed the following areas must be more closely researched:

Rock samples for testing purposes were obtained from drill core and were suitable for a limited study such as this. However, in an operating mine, where shafts and development roads will encounter a greater variety of formations and greater accuracy and certainty will be required, a more wide ranging test program will have to be initiated. Not only will this require many more samples but testing will have to be performed under conditions of natural moisture and saturation to take into account the effects of large quantities of water if hydraulic breakage is used. Investigations will also have to look at time dependant behaviour of both coal and adjacent strata since permanent pillars will probably be used between mine panels to increase mine stability. A field testing program will have to be designed that is related to the mining method so that the maximum possible information can be gained in the sensitive areas of the excavation.

The finite element analysis provides an approximate appraisal of how stresses will be redistributed around the excavations and identifies potential problem areas. The findings show some agreement with reported observations in operating mines. This method of analysis can be made considerably more realistic with more sophisticated computer programs if the initial property data is available. Non-linear, elasto-plastic and plastic analysis and the

simulation of joints and faults are just some of the options available with the finite element method. Reliability with this kind of analysis will only be achieved when an underground district, such as at Kaiser Resources' mine, can be fully instrumented and the resulting data used to verify and improve the accuracy of theoretical techniques.

The physical model studies illustrate the types of failure that are active and where they may occur. Although scaling of strength and deformational properties is incorporated only a qualitative assessment of behaviour can be obtained. Three dimensional physical modelling has been employed for analysis around openings in longwall mines with realistic results.²² If physical modelling is to be developed for sublevel mine analysis, three dimensional techniques must be used to determine the interaction between extracted stopes and adjacent pillars, and the developing sublevels below.

Any technique that provides greater understanding of excavation behaviour in underground mining situations is useful. Both the mathematical and physical model analyses have been shown to be useful in identifying probable locations in which problems will occur. In the future there will be an increasing adoption of this kind of technique which will do its part in trying to reduce the risks inherent in any new mining venture.

TEST RESULTS UNIAXIAL SAMPLE 5

Coal Triaxial Tests - Mohr Circle Diagrams
Samples 1, 2 and 4
Angle of Internal Friction = 19°

Siltstone Samples 13 - 14
Triaxial Strength Tests - Mohr Circle Analysis
Angle of Internal Friction = 42°
 $C = 15 \text{ MPa}$

Sandstone Samples 17 - 20
Triaxial Strength Tests - Mohr Circle Analysis
Angle of Internal Friction = 50°
 $C = 30$ MPa

APPENDIX II
SAMPLE CALCULATION
OF LOADING
CONDITIONS

The load to be applied at each nodal point on the boundary of an excavation was calculated by the following graphical method.

The magnitude of the vertical stress at each node is obtained from the initial stress distribution and is represented by the line AB. The area of loading for each node extends either side of the node to the midpoints between the adjacent nodes. The average stress along the area under consideration is multiplied by the area to give the load on that node.

e.g. node 155

$$\text{Area} = 2.5 \times 1 = 2.5 \text{ m}^2$$

$$\text{Average Stress} = 5.15 \text{ MPa}$$

$$\text{Load} = 5.15 \times 2.5 = 12.875 \text{ MN}$$

This process is repeated for all the nodes and the horizontal loads on the other faces are calculated in a similar manner.
